(Received January 20, 1999; Accepted July 28, 1999)

**Abstract.** Molecular evolution of the chloroplast noncoding region between the *atpB* and *rbcL* genes was investigated in the moss family Hylocomiaceae. Nucleotide substitution contributed to most of the variation among taxa, although an insertion of 29 base pairs was found in *Rhytidiopsis robusta*. The evolution of *atpB-rbcL* intergenic spacer was constrained in Hylocomiaceae compared to the evolutionary rates of this chloroplast spacer, and even of the *rbcL* gene, in angiosperms. Using a relative rate test procedure, substitution rates of the chloroplast spacer were found to be consistent with the hypothesis of a molecular clock, except for three taxa. Based on previous knowledge of the evolutionary rate of this spacer in true mosses, the divergence of the Hylocomiaceae from their common ancestor was estimated to be 29.0 million years ago, which is consistent with the fossil record. The chloroplast sequences supported the monophyly of the Hylocomiaceae with a bootstrap value of 82%. The effects of long branch attraction caused the erroneous placements of *Rhytidiopsis* and *Rhytidium* in the parsimony analysis. In contrast, neighbor-joining analysis provided a more congruent estimate of the phylogeny of the Hylocomiaceae based on the cpDNA variation observed.

**Keywords:** *atpB-rbcL* intergenic spacer; Chloroplast DNA; DNA sequence; Gene tree; Hylocomiaceae; Long branch attraction; Molecular clock; Mosses.

## Introduction

The *atpB-rbcL* spacer, a noncoding region of the chloroplast genome, has been recently used in phylogenetic studies of angiosperms (Golenberg et al., 1993; Manen et al., 1994b), such as the Betulaceae (Bousquet et al., 1992a), Celastrales (Savolainen et al., 1994) and Rubiaceae (Manen et al., 1994a; Manen and Natali, 1995; Natali et al., 1995), as well as of mosses (Chiang, 1994). The length of the spacer region varies from 519 to 557 base pairs in true mosses, which is longer than in the liverwort *Marchantia polymorpha*. The evolution of the *atpB-rbcL* spacer sequence of the true mosses (Chiang, 1994) is constrained relative to the spacer in angiosperms as well as to the *rbcL* gene in angiosperms (Zurawski et al., 1984; Manen and Natali, 1995).

In a previous study, the evolution of the chloroplast *atpB-rbcL* spacer in 11 families of true mosses was analyzed (Chiang, 1994). At this broad level, the spacer evolved at a rate consistent with the hypothesis of a molecular clock. In this study, we investigated the tempo and mode in evolution of the *atpB-rbcL* chloroplast spacer within the family Hylocomiaceae, which are widespread in temperate regions and occur on high mountains in the tropics (Rohrer, 1985). The phylogenetic relationships among

genera in this family have been determined based on the sequences of both the internal transcribed spacers of nuclear ribosomal DNA and the *atpB-rbcL* chloroplast spacer (Chiang, 1994). In contrast to a cladistic analysis based on morphological traits of the Hylocomiaceae (Rohrer, 1985), which recognized 12 genera, our study excluded six genera [i.e. *Pleurozium*, *Rhytidiadelphus*, *Macrothamnium*, *Orontobryum*, *Leptohymenium*, and *Leptocladiella* (cf. Chiang, 1995)] from the family. In addition, *Thelia*, a genus endemic to North America, was included as a member of the Hylocomiaceae based on molecular evidence (Chiang, 1994), bringing the genus number of the family up to seven.

This study had four goals: 1) to reconstruct the gene tree of the *atpB-rbcL* spacer in the family Hylocomiaceae; 2) to investigate the evolutionary rates of this spacer; 3) to test the hypothesis of a molecular clock; and 4) to estimate the time of divergence from a common ancestor of the Hylocomiaceae.

## Materials and Methods

### Plant Materials

According to a previously inferred phylogeny, eleven species of seven genera have been included in the Hylocomiaceae (Chiang, 1994). For the current study, all species of the Hylocomiaceae as well as two outgroup taxa, *Pleurozium schreberi* (Brid.) Mitt. and *Entodon seductrix* (Hedw.) C. Muell., were included (Table 1)

<sup>3</sup>Corresponding author. Tel: +886-6-2757575 ext. 65525; Fax: +886-6-2742583; E-mail: tychiang@ccvax.sinica.edu.tw

**Table 1.** List of taxa examined in this study and the voucher specimens (cf. Rohrer 1985; Chiang, 1994).

Taxa	Localities	Vouchers
Ingroups: Family Hylocomiaceae		
<i>Hylocomium splendens</i> (Hedw.) B. S. G.	North Carolina, USA	Chiang 31091
<i>Hylocomiastrum umbratum</i> (Hedw.) Fleisch.	North Carolina, USA	Chiang s.n.
<i>H. pyrenaicum</i> (Spruce) Lindb.	British Columbia, Canada	Vitt 34097
<i>Loeskeobryum brevirostre</i> (Brid.) Fleisch.	North Carolina, USA	Chiang s.n.
<i>L. cavifolium</i> (Lac.) Fleisch.	Mt. Fuji, Japan	Inoue 935
<i>Neodolichomitra yunnanensis</i> (Besch.) T. Kop.	Yunnan, China	He 30880
<i>Rhytidiopsis robusta</i> (Hook.) Broth.	Washington, USA	Chiang 198
<i>Rhytidium ruginosa</i> (Hedw.) Kindb.	Sichuan, China	Redfearn 35492
<i>Thelia asprella</i> Sull.	Missouri, USA	Allen 13398
<i>T. hirtella</i> (Hedw.) Sull.	Florida, USA	Allen 8566
<i>T. lescurii</i> Sull.	Alabama, USA	Willis 126
Outgroup:		
<i>Pleurozium schreberi</i> (Brid.) Mitt.	Sichuan, China	Whittemore 3969
<i>Entodon seductrix</i> (Hedw.) C. Muell	Missouri, USA	Crosby s.n.

(Chiang, 1994). Plants of four taxa—*Hylocomium splendens* (Hedw.) B. S. G., *Hylocomiastrum umbratum* (Hedw.) Fleisch., *Rhytidiopsis robusta* (Hook.) Broth., and *Loeskeobryum brevirostre* (Brid.) Fleisch.—were collected from field locations within the United States and air-dried without special field treatment. Herbarium specimens of other taxa were used for DNA isolation (Table 1). At least two samples from different populations were sequenced for ingroup species. Since no variation of this *atpB-rbcL* noncoding spacer in mosses has been found within species, only one sequence of each taxon was included in the analysis (Chiang, 1994). Voucher specimens are in the herbarium of the Missouri Botanical Garden (MO).

#### DNA Extraction and Sequencing

Leaf tissue from single individuals was frozen in liquid nitrogen and ground in Eppendorf tubes with a metal dounce. Genomic DNAs were extracted from the powdered tissue in 600 µl 2X CTAB buffer (Murray and Thompson, 1980) with 0.4% (v/v) *b*-mercaptoethanol and incubated for 1 h at 65°C. After adding equal volumes of 24:1 chloroform: isoamyl alcohol, the tissue mixture was centrifuged at 14,000 rpm for 15 min at room temperature. The supernatant was transferred to an Eppendorf tube followed by addition of 1.2 ml of absolute ethanol. After overnight incubation at 4°C, DNA was recovered by centrifuging the mixture at 14,000 rpm for 15 min at 4°C. The brown to black DNA pellet was rinsed in 70% ethanol and centrifuged for 5 min at 10,000 rpm. The DNA pellet was resuspended in 20 µl TE.

The extracted genomic DNA was purified on a low-melt agarose gel to remove secondary compounds and RNAs. The band containing the DNA of the correct size was cut out of the gel and transferred to an Eppendorf tube. Equal weights of distilled water were added to the gel block containing the purified DNAs. Prior to use of the DNAs for PCR, the gel was heated in a 65°C water bath for 3 min.

Two primers (Chiang et al., 1998), *rbcL-1* and *atpB-1*, were developed for amplifying and sequencing the *atpB-rbcL* spacers from the sequences of *Marchantia* (Umesono et al., 1988), tobacco (Shinozaki et al., 1986) and rice (Nishizawa and Hirai, 1987).

PCR reactions were carried out using *Taq* polymerase (Promega) at an annealing temperature of 57°C. PCR products were polyacrylamide-gel-purified and sequenced by the dideoxy-mediated chain-termination method (Sanger et al., 1977). The *fmoI*<sup>TM</sup> DNA Sequencing System (Promega), which uses *Taq* polymerase, was used for sequencing. The detergent NP-40 was added to assist sequencing through G-C rich regions and secondary structure (Wang et al., 1992). Both strands of DNA were sequenced with about a 50 base overlap.

#### Data Analysis

**Sequence alignment.** Sequences were aligned by multiple alignments without weighting transversions or transitions using the Clustal V Program (Higgins et al., 1992) and later adjusted visually. The fixed gap penalty was 35 and the floating penalty was 4.

**Phylogenetic analyses.** Cladistic analyses of the *atpB-rbcL* sequence data were performed using a maximum parsimony criterion (PAUP, Version 3.1.1., Swofford, 1993) and by Neighbor-Joining (NJ) (MEGA, Version 1.01, Kumar et al., 1993). Parsimony analyses were conducted using heuristic searches with TBR branch swapping, accelerated transformation (ACCTRAN), stepwise addition of 10 random replicates, an unconstrained number of maximum trees, and retention of multiple most parsimonious trees (MULPARS). Indels were recognized as additional characters, and all characters were unweighted. Both strict (Sokal and Rohlf, 1981) and 50% majority-rule (Margush and McMorris, 1981) consensus trees were rooted at *Pleurozium* and *Entodon*. Neighbor-joining analyses were conducted using Kimura's (1980) 2-parameter distance.

A *gI* test (Huelsenbeck, 1991) of skewed tree-length distribution was calculated from 10,000 random trees generated by PAUP in order to measure the information content of the data. Critical values of the *gI* test were obtained from Hillis and Huelsenbeck (1992). The fit of character data on phylogenetic hypotheses (Swofford, 1991) was evaluated by the consistency index, CI (Kluge and Farris, 1969) and the retention index, RI (Archie, 1989; Farris, 1989). The statistical significance of the CI was determined according to the method of Klassen et al. (1991). Confidence in the clades was tested by bootstrapping (Efron, 1982; Felsenstein, 1985) with 400 replicates (Hedges, 1992) of heuristic searches on the 50% majority rule trees. The nodes with bootstrap values >0.70, as a rule of thumb, were considered significantly supported with 95% probability (Hillis and Bull, 1993).

*Tests of taxonomic congruence and alternative trees.* The phylogeny inferred from the chloroplast spacer sequence represents a gene phylogeny and may conflict with the organismal tree. In this study, a reconstructed most parsimonious phylogeny of Hylocomiaceae inferred from the combined data of ITS rDNA and *atpB-rbcL* sequences (Chiang, 1994) was taken as the organismal tree. To test the taxonomic congruence between topologies as well as gene trees versus the organismal tree, a nonparametric Wilcoxon sign-ranked test was employed (Templeton, 1983). Two-tailed probabilities were used to examine significance levels (Felsenstein, 1985; statistical tables see Sokal and Rohlf, 1981). The information on characters favoring each tree, with the direction of different steps according to the assumption of parsimony, was obtained from the computer program MacClade (Maddison and Maddison, 1992).

*Relative rate tests.* The hypothesis of a molecular clock (Zuckerlandl and Pauling, 1965) was tested by a relative rate test (Sarich and Wilson, 1973; Wu and Li, 1985). The total number of nucleotide substitutions (K), which is the number of transitional and transversional substitutions per site, was calculated from each lineage using *Pleurozium*

as the reference species. The data on the number and ratio of transversions versus transitions between taxa was obtained from MEGA. The null hypothesis of a molecular clock predicts that the number of nucleotide substitutions between two lineages will be the same. Based on the assumption of a normal distribution of nucleotide substitutions (Wu and Li, 1985), the hypothesis of a molecular clock will be rejected with 95% significance when the difference of substitution rates between two lineages is greater than 1.96 times the standard error.

## Results

### Nucleotide Sequences and Variation

The length of the *atpB-rbcL* spacer varies from 553 (*Hylocomium splendens*) to 587 (*Rhytidiopsis robusta*) base pairs within the Hylocomiaceae. The spacer of *Entodon* is shorter (549 base pairs) than that of ingroup taxa and the other outgroup *Pleurozium* (555 base pairs). Sequence alignment is shown in Figure 1. This noncoding chloroplast spacer is highly A+T rich (37.7% A and 42.4% T, on average). This agrees with data from most noncoding spacers and pseudogenes (Li, 1997).

Of 671 positions of the aligned sequences of the noncoding spacer, 289 are variable (43.1%); 226 substitutions occur in only a single taxon (autapomorphies); and 67 bases (10.0% of total) are informative for phylogenetic reconstruction. Insertions/deletions (indels) are a common phenomenon in the chloroplast spacer of the Hylocomiaceae and the outgroup taxa. Of 330 indel events, based on pairwise comparisons, 249 (75.5%) are single base indels, 49 (14.8%) are 2- to 5-base indels; and 20 (6.0%) are 6- to 9-base indels. Several insertions were identified: a four base insertion (TTAG, 212-215) in *Thelia hirtella*; a 4-base insertion (GAAT, 255-258) in *Loeskeobryum brevirostre*; a 6-base insertion (AGATTA, 451-456) in *Hylocomiastrum umbratum*; a 9-base insertion (499-507) in the species of *Thelia* and *Neodolichomitra*; and a 29-base insertion (342-370) in *Rhytidiopsis robusta*.

**Table 2.** Numbers of transitions/transversions (above diagonal) and their ratios (below diagonal) between taxa. 1, *Thelia hirtella*; 2, *T. lescurii*; 3, *T. asperella*; 4, *Rhytidiopsis*; 5, *Rhytidium*; 6, *Hylocomium*; 7, *Loeskeobryum brevirostre*; 8, *L. cavifolium*; 9, *Hylocomiastrum umbratum*; 10, *Hylocomiastrum pyrenaicum*; 11, *Neodolichomitra*; 12, *Pleurozium*; 13, *Entodon*. Both *Pleurozium* and *Entodon* were chosen as outgroups.

**Figure 1.** Alignment of nucleotide sequences of *atpB-rbcL* spacer of the chloroplast DNA of the Hylocomiaceae and outgroups.

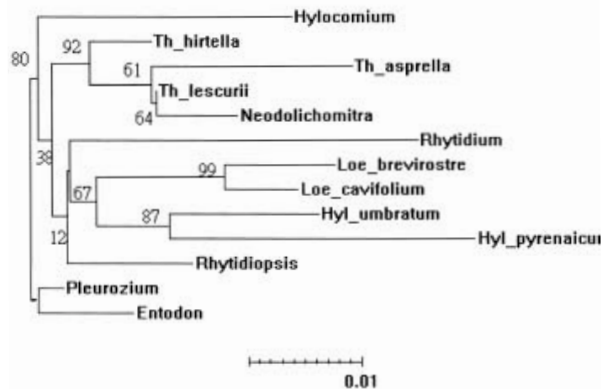

Based on pairwise comparisons conducted by the MEGA program, a total of 1,627 nucleotide substitution events occurred between the taxa of Hylocomiaceae and the outgroups, of which 812 were transitions and 815 were transversions (Table 2). The ratio of transitions to transversions is 0.996 ( $\approx 1.0$ ), which is very close to the ratio ( $Ti/Tv = 0.97$ ) in the tribe Rubieae (Manen and Natali, 1995). The transitions/transversions ratio for pairwise comparisons between taxa is highly variable (Table 2) ranging from 0.14 to 3.00. Nevertheless, most of the ratio of transitions to transversions is higher than the expected value of 0.5 and shows a bias favoring transitions.

### Phylogenetic Reconstruction

Six equally parsimonious trees of 257 steps were identified by parsimony analysis, with a CI of 0.825 ( $P \leq 0.05$ ), and a RI of 0.657; a strict consensus tree is shown in Figure 2. A *gI* statistic of -1.05 indicated significant structure within the data ( $P \leq 0.05$ ). Nevertheless, resolution was incomplete: a trichotomy of *Loeskeobryum*, *Hylocomiastrum*, and the *Rhytidopsis* clade remained unresolved (Figure 2). Six nodes were strongly supported with significant bootstrap values: the Hylocomiaceae (75%); *Loeskeobryum* (100%); *Hylocomiastrum* (84%); the clade of *Rhytidium*, *Neodolichomitra*, and *Thelia* (73%); the clade of *Neodolichomitra* and *Thelia* (98%); and the clade

**Figure 2.** Strict consensus tree obtained from PAUP on *atpB-rbcL* spacer sequence in the Hylocomiaceae, with bootstrap values at nodes.

**Figure 3.** NJ tree of the Hylocomiaceae based on *atpB-rbcL* spacer sequence, with bootstrap values at nodes.

of *Thelia lescurii*, *T. asprella*, and *Neodolichomitra* (70%).

Neighbor-joining analyses were conducted on the K2P distance matrix (Table 3). A tree was obtained (Figure 3), which mostly agreed with the organismal tree based on sequences of both nrITS and cpDNA *atpB-rbcL* spacer (Chiang, 1994), except for the position of *Neodolichomitra*. The organismal tree supported the monophyly of both *Thelia* [(*T. hirtella*, *T. asprella*), *T. lescurii*] and *Neodolichomitra*. In contrast, in the NJ tree, *Neodolichomitra* was nested in *Thelia* species as well as with parsimony analysis. Obviously, branches leading to *Rhytidiopsis*, *T. hirtella*, and *T. lescurii* were much shorter than the ones leading to their sister taxa. The topology of the NJ tree was not fully congruent with the parsimony trees. In the NJ tree, *Rhytidium* and *Rhytidiopsis* were more closely related to *Hylocomiastrum* instead of *Thelia* as indicated by the parsimony tree. As in the parsimony tree, the monophyly of the Hylocomiaceae and four other clades was significantly supported (Figure 3).

## Discussion

### Phylogeny Reconstruction

The monophyly of Hylocomiaceae was significantly supported. However, the cladistic analyses did not resolve the generic relationships completely or in a proper manner. Unexpectedly, the various analyses of the chloroplast spacer suggested a nested relationship between *Neodolichomitra* and *Thelia*, in contrast to the organismal tree (Chiang, 1994). The Wilcoxon signed-rank tests, with three characters favoring the NJ tree and two characters favoring the organismal tree ( $T_s = 6.00$ ,  $P < 0.1$ , n. s.), indicated the difference to be non-significant. In contrast, 21 characters favored the parsimonious chloroplast tree, and none favored the organismal tree. A  $T_s$  statistic value of 0.00 ( $P \leq 0.001$ ) obtained from the sign-ranked tests indicated a significant difference between the two trees.

Based on the Wilcoxon sign-ranked tests, in this study, the NJ tree was found to be more congruent with the organismal tree than was the parsimony tree. Apparently,

the lack of congruence between the parsimony tree and the NJ tree (or the organismal tree) was caused by the taxa with shorter branches, including *Rhytidiopsis* and *Thelia lescurii*. Branch attraction (cf. Swofford et al., 1996) might have caused the erroneous placement of *Rhytidiopsis* and *Rhytidium* in the parsimony trees. That is, *Rhytidiopsis* and *Rhytidium* might have been artificially attracted to the *Thelia* clade.

### Molecular Evolution

The numbers of nucleotide substitutions per site between the Hylocomiaceae and *Pleurozium* varied from 0.0237 to 0.0444 with an average of 0.0336. It is noteworthy that the rates of substitution of the noncoding *atpB-rbcL* spacer of mosses are much slower than in vascular plants. For example, the rate of nucleotide substitution is 0.0691 between maize and barley (Zurawski et al., 1984), and 0.027 among 15 Rubieae species (Manen and Natali, 1995).

One might expect that a noncoding region such as the *atpB-rbcL* spacer should evolve faster than a coding sequence, such as the *rbcL* gene, due to weaker functional constraints. For unknown reasons however, the evolution of the noncoding regions seems constrained in angiosperms (Zurawski et al., 1984) relative to the third codon position for *rbcL*. In Hylocomiaceae, the substitution rate for the chloroplast noncoding spacer ( $K = 0.012$ ) appears to be much slower than that of the third ( $K = 0.135$ ), as well as the first ( $K = 0.0360$ ) and second ( $K = 0.0190$ ) codon positions for *rbcL* between barley and maize (Bousquet et al., 1992b). Undoubtedly, the evolutionary history of the Hylocomiaceae is much longer than that between barley and maize, which results in much lower rates of substitution per year. Similar observations have been made in the Rubieae (Manen and Natali, 1995), for which the evolutionary rate of the *atpB-rbcL* spacer ( $K = 0.027$ ) was close to that of *rbcL* gene ( $K = 0.021$ ).

Among the taxa analyzed, the chloroplast spacers of *Thelia hirtella*, *T. lescurii*, and *Rhytidiopsis robusta*

evolved relatively slowly. When pairwise relative rate tests were conducted using *Pleurozium* as a reference species, most lineages fit the hypothesis of a molecular clock, except for the above three species (Table 4).

In a previous study (Chiang, 1994), the evolutionary rate of the chloroplast *atpB-rbcL* spacer in true mosses was estimated to be  $2.24 \pm 0.039 \times 10^{-10}$  substitutions per site per year. Based on the molecular clock hypothesis and the average rate of nucleotide substitutions ( $K = 0.013$ ), which was recalculated with exclusion of the above three slowly evolving taxa (cf. Savard et al., 1994), the divergence of Hylocomiaceae from their common ancestor could be estimated at 29 million years ago. Usually, molecular clock divergence dates are expected to precede, more or less slightly, dates derived from the fossil record because gene divergence precedes morphological divergence and because the diverging phylla have to become ecologically quite abundant before being detected in fossilized sediment strata (Savard et al., 1994). In this study, the divergence estimated from the molecular clock also preceded the earliest fossil records of this family (23 million years ago; Miller, 1984).

Despite its slow evolutionary rate, the *atpB-rbcL* spacer did provide information to resolve the phylogeny at generic and lower levels. Natali et al. (1995) used this noncoding spacer to reconstruct the phylogeny of the tribe Rubieae, in which the monophyly of both the Rubieae and the subfamily Rubioideae was significantly supported. This noncoding spacer of chloroplast DNA has also been found informative in inferring the phylogeny of Betulaceae, which agreed with phylogenies derived from *rbcL* and morphological characters (Bousquet et al., 1992a). In our study, the monophyly of Hylocomiaceae was supported significantly based on bootstrap estimates, and variation was even detected between species. Although the generic relationships estimated from parsimony contradicted part of the organismal tree, the neighbor-joining analysis provided a more congruent estimate of the phylogeny.

**Table 4.** Relative rate differences between species pair ( $K_{13}$ - $K_{23}$ ; above diagonal) and the ratios of the relative rate differences to standard errors (below diagonal); taxa numbered as in Table 2. *Pleurozium* was used as outgroup taxon in all pairwise relative rate tests.

## 葉綠體 DNA 介於 *atpB* 及 *rbcL* 基因間的非轉譯區間 在塔蘚科的分子演化

蔣鎮宇<sup>1</sup> Barbara A. Schaal<sup>2</sup>

<sup>1</sup>國立成功大學生物學系

<sup>2</sup>美國華盛頓大學生物學系

本研究探討葉綠體 DNA 中一個介於 *atpB* 及 *rbcL* 基因間的非轉譯區間在塔蘚科植物的分子演化，種間的遺傳變異大多來自核甘酸的置換，雖然一個 29 bp 的插入發生在 *Rhytidiopsis robusta*, *atpB-rbcL* 基因區間的演化速率在塔蘚科中相較於被子植物中，或被子植物的 *rbcL* 基因還要緩慢，根據相對速率測驗，此 DNA 片段的演化符合分子時鐘的假說。依據在真蘚植物中已知的分子演化速度，塔蘚植物的起源可以追溯至二千九百萬年前，並與化石證據吻合。此基因片段支持塔蘚科植物為一單一起源的分類群，然而，在最大簡約分析中因長支吸引效應，使得 *Rhytidiopsis* 及 *Rhytidium* 發生錯誤的分類，相對地，相鄰連接分析法在重建親緣歷史上有較可靠的估算。

**關鍵詞：***atpB-rbcL* 基因間的區間片段；葉綠體 DNA；分子序列；基因樹；塔蘚科；長枝吸引；蘚類；分子時鐘。
